SAP® MaxDB[™] Analysis of SQL Locking Situations

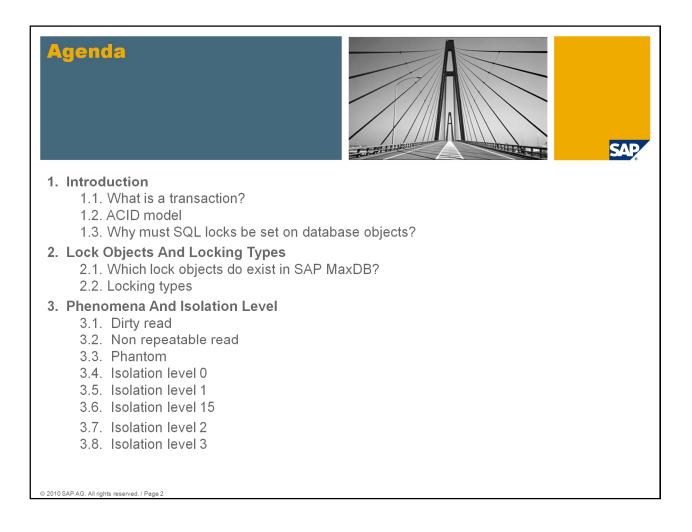

Expert Session 12

SAP

MaxDB/liveCache Development Support Christiane Hienger Bettina Laidler September 7, 2010

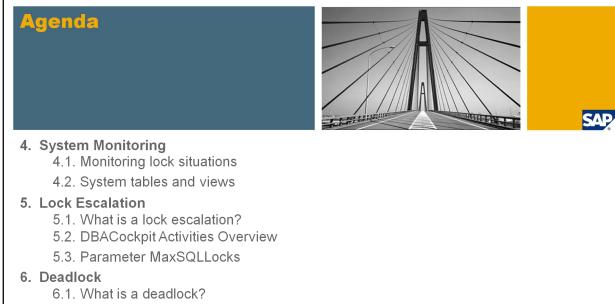

THE BEST-RUN BUSINESSES RUN SAP™

The target group of this session are customers with SAP Applications running on SAP MaxDB, SAP partners and SAP employees who support SAP MaxDB customers .

This session is based on MaxDB version 7.8 database called EXPERTDB which is integrated into the internal development System S70.

This session consists of an theoretical part and a second practical part where analysis of lock situation are shown.

- 6.2. Demo with DeadlockDetectionLevel = 4
- 6.3. Demo with DeadlockDetectionLevel = 0

A transaction is a sequence of one or more processing steps (SQL commands). It refers to database objects such as tables, views, joins, and so on. The database modifications must follow an "all or nothing" rule. If one part of the transaction fails, the entire transaction fails.

When all SQL commands of a transaction are executed successfully the transaction can be closed with COMMIT work.

If errors happen during the processing of a transaction the entire transaction will be rolled back.

The next slides show the requirements which must be fulfilled (ACID condition = atomic, consistent, isolation, durable).

The ACID model is one of the oldest and most important concepts of database theory. It sets forward four goals: atomicity, consistency, isolation and durability. No database that fails to meet any of these four goals can be considered reliable.

Indivisibility (atomic):

A transaction is atomic, which means that it is either executed completely (all its operations) or not at all (all or nothing principle).

For example: There is no employee without a salary.

Maintaining consistency:

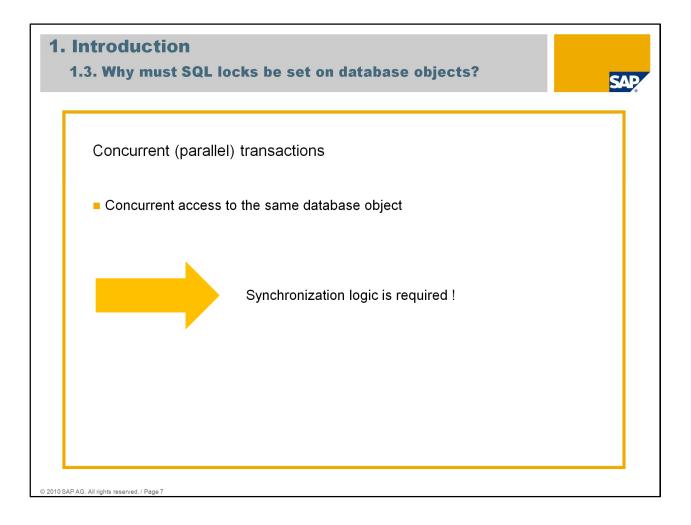

The defined integrity conditions remain fulfilled, for example, each employee has a personnel number.

Isolation:

The operations within the transaction are isolated from the operations of other transactions.

Durability:

Changes that completed transactions made to objects must be permanent (persistent), for example, even if a system crashes.

If several transactions want to access the same objects concurrently, these accesses must be synchronized with the help of lock management.

Since the database system allows concurrent transactions to access the same database objects, locks are required to isolate individual transactions.

To lock an object means to lock this object from certain forms of use by other transactions.

The more locks that are set, and the longer these stay in place, the less concurrency is possible in database operation.

All locks are released by the end of the transaction at the latest. (COMMIT, ROLLBACK, COMMIT WORK RELEASE, ROLLBACK WORK RELEASE).

Agenda

2.1. Which	lock objects do e	xist in SAP MaxDB?	S
Locki	ing objects are		
	■Table rows ■Tables ■Database catale	(ROW) (TAB) og (SYS)	
Activ	ation		
	 Implicit Explicit 		

Locking management handles three types of objects:

- Records (ROW) Individual lines of a table are locked
- Tables (TAB) The entire table is locked.
- Database catalog entries (SYS) Database catalog entries are locked.

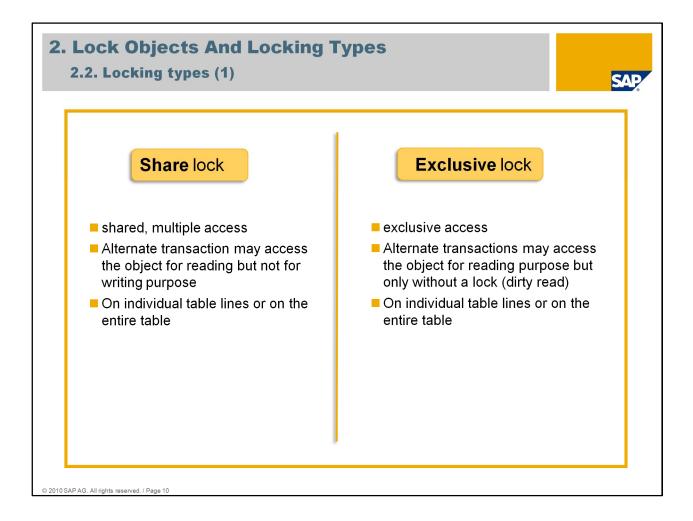

Locks can be requested implicitly by the database system or explicitly by you (using the relevant SQL statements).

Requesting locks implicitly:

All modifying SQL statements (for example INSERT, UPDATE, DELETE) always request an exclusive lock. You can select the lock operation mode by specifying an **isolation level** when you open the database session. Depending on the specified isolation level, locks are then implicitly requested by the database system when the SQL statements are processed.

Requesting locks explicitly:

You can assign locks explicitly to a transaction using the LOCK statement, and you can lock individual table lines by specifying a LOCK option in an SQL statement. This procedure is possible at each **isolation level**. In addition, you can use the LOCK option to temporarily change the isolation level of an SQL statement.

What is a shared lock (Read Locks)?

Shared locks allow other transactions to perform read accesses but not to perform write accesses to the locked object. Other transactions can set further shared locks on this object, but no exclusive locks.

Shared locks can be set on individual table lines or on the entire table.

What is an exclusive lock (Write Locks)?

If an exclusive lock on a database object is assigned to a transaction, other transactions cannot access this object.

Transactions that want to check whether exclusive locks exist or to set exclusive or shared locks collide with the existing exclusive

lock of the other transaction. They cannot access the locked object.

Exclusive locks can be set on individual table lines or on the entire table.

2. Lock Objects And Locking Types

2.2. Locking types (2)

Can an alternate	EXCL	SHARE	EXCL	SHARE	EXCL	SHARE
transaction ?	Table lo	ck	Row loc	k	Catalog	lock
lock this table EXCLUSIVE	NO	NO	NO	NO	NO	YES
lock this table SHARE	NO	YES	NO	YES	NO	YES
lock any row of this table EXCLUSIVE	NO	NO			NO	YES
lock an already locked row EXCLUSIVE			NO	NO		
lock another row EXCLUSIVE			YES	YES		
lock any row of this table SHARE	NO	YES			NO	YES
lock a row SHARE			NO	YES		
lock another row SHARE			YES	YES		
change the table definition in the catalog	NO	NO	NO	NO	NO	NO
read the table definition from the catalog	YES	YES	YES	YES	NO	YES

The above table provides an overview of possible parallel read locks (share locks) and write locks (exclusive locks).

A lock collision exists in the cases which are marked with "No"; i.e., after having requested a lock within a transaction, the user must wait for the lock to be released until one of the above situations or one of the situations that are marked with "Yes" in the matrix occurs.

Additionally, the following applies:

- If no lock has been assigned to a transaction for a data object, then a shared or exclusive lock can be requested within any transaction, and the lock is immediately assigned to the transaction.
- If a shared lock has been assigned to a transaction T for a data object, and if no lock has been assigned to any concurrent transaction for this data object, then the transaction T can request an exclusive lock for this data object and the lock is immediately assigned to this transaction.
- If an exclusive lock has been assigned to a transaction for a data object, then a shared lock can, but need not be requested for this transaction.

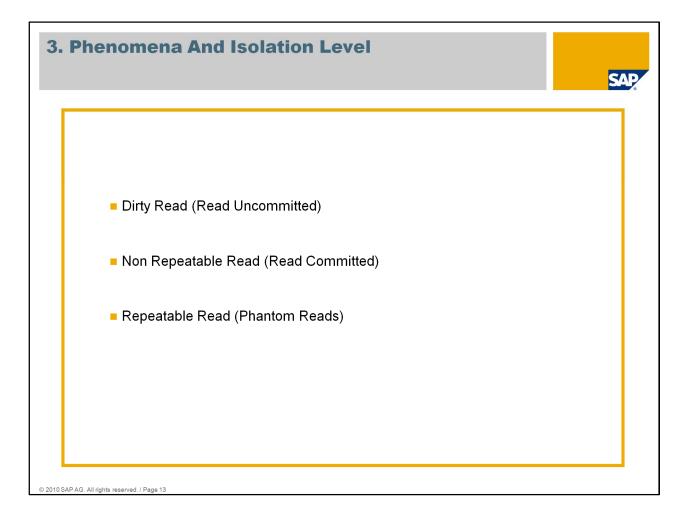

Agenda

- 3. Phenomena And Isolation Level
- 4. System Monitoring
- 5. Lock Escalation
- 6. Deadlock
- 7. Which Application Blocks The System?
- 8. Summary

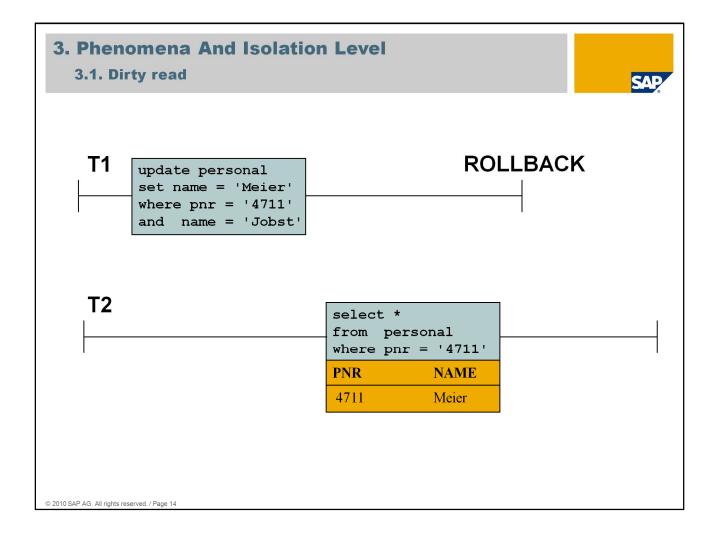

. _____All rights reserved. / Page 12

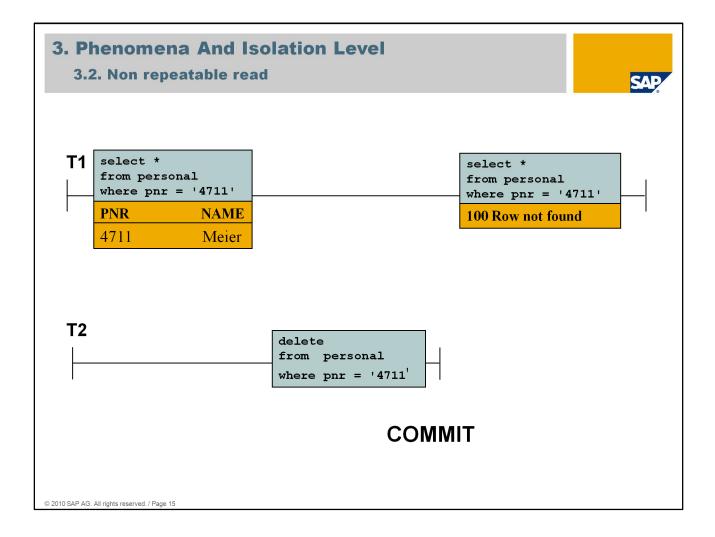

The **isolation level** plays an important role in the lock activities of the database system. You use the isolation level to specify whether locks are requested or released implicitly, and how.

Your choice of isolation level affects the degree of parallelism of concurrent transactions and the consistency of the data: **the lower the value of the isolation level, the higher the degree of parallelism**, and the lower the degree of guaranteed consistency.

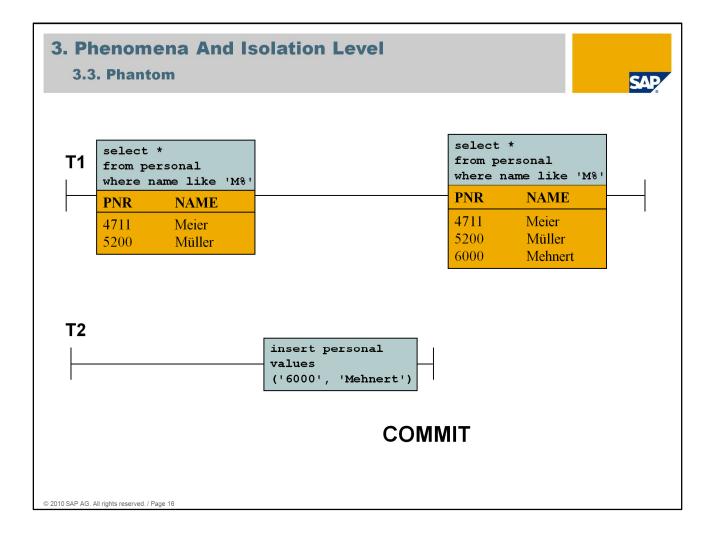

If transactions are competing for access to the same data, then different isolation levels can cause different sorts of inconsistencies. You can find a compromise between parallelism and consistency, while taking into account the requirements of your database application.

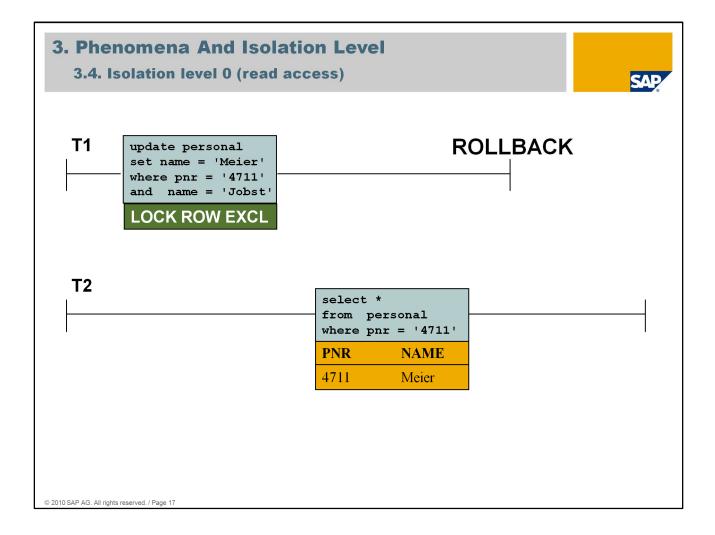

A row is modified in the course of a transaction T1, and a transaction T2 reads this row before T1 has been concluded with the COMMIT statement. T1 then executes the ROLLBACK statements. In this case, T2 read a row that never actually existed.

Transaction T1 reads a row. Transaction T2 then modifies or deletes this row, and completes the action with the commit statement. If T1 then reads the row again, it either gets the modified row or a message indicating that the row no longer exists.

Transaction T1 executes an SQL statement S that reads a set of rows (M) fulfilling a search condition. Transaction T2 then inserts or modifies data, and produces another row that fulfills this search condition. If T1 then executes the statement S again, the set of rows that is read differs from the set M.

Isolation level 0 does not offer any protection against access anomalies.

When rows are inserted, updated or deleted, **implicit exclusive locks** are assigned to the transaction for the rows affected (T1).

These cannot be released until the end of the transaction.

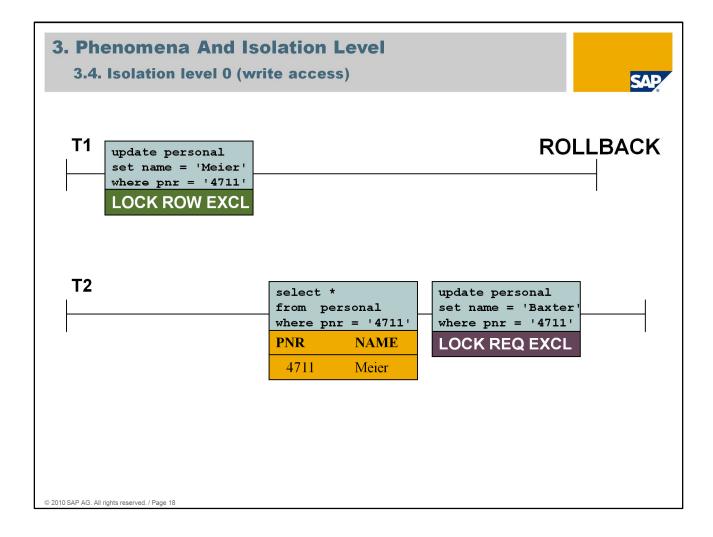

Read access:

If you specify the isolation level 0 (uncommitted), then rows are **read without shared locks** being requested implicitly.

If a row is then read twice within a transaction, this isolation level does not guarantee that the row has the same state the second time as the first, since it could have been changed by a competing transaction between the two reads. Furthermore, there is no guarantee that the state of a row that was read has already been recorded in the database using a COMMIT WORK statement.

It is not guaranteed that:

- a repeated read within the same transaction returns the same result
- rows once read ever will be committed (become persistent)

When rows are inserted, updated or deleted, **implicit exclusive locks** are assigned to the transaction for the rows affected.

These cannot be released until the end of the transaction.

Write access:

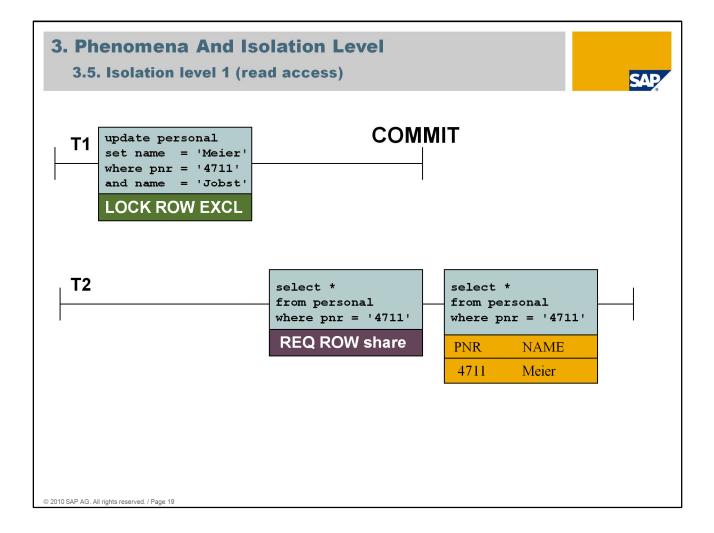

Rows have to be exclusively locked before writing (Insert, Update, Delete)

LOCK ROW EXCL -> transaction got the exclusive lock on the row (T1) LOCK REQ EXCL -> transaction is waiting for an exclusive lock (T2)

Locks are kept until the end of transaction, so that

- no concurrent modifications can take place
- this status can be made persistent (committed)

For SAP applications (ABAP stack), the isolation level is defined in the XUSER file. The ABAP applications run at isolation level 0. To avoid the phenomena caused by isolation level 0 ABAP programming (Open SQL) offers an own locking mechanism so called enqueue lock objects.

When you retrieve data using an SQL statement, the database system ensures that, **at the time each row is read, no exclusive lock has been assigned to other transactions** for the given row. However, it is impossible to predict whether an SQL statement causes a shared lock for a row of the specified table and for which row this may occur. As of SAP MaxDB version 7.4 the share lock is removed after the record has been read.

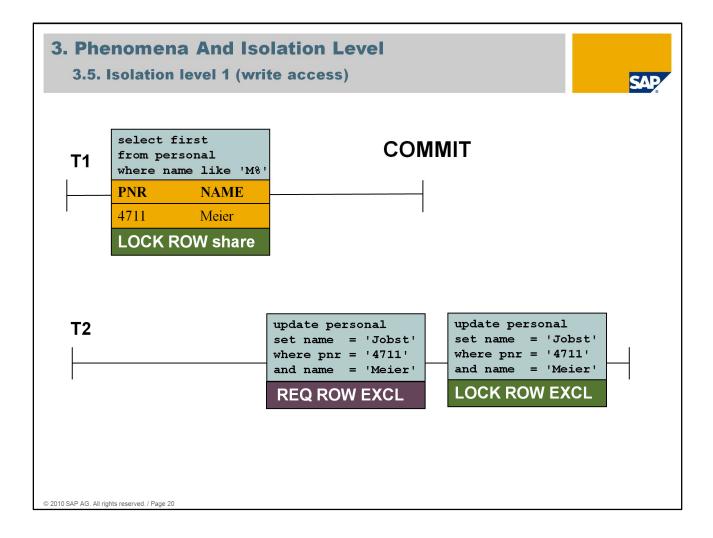

Locking of data entities and optimal multi-user operation are in direct conflict with one another. It is not recognizable whether the waiting user is waiting for a lock or whether the system is running poorly.

Read Access:

Read persistent (committed) rows. Check for collision happens before reading

In case of a collision a lock request is set. (REQ ROW SHARE)

The lock dispatcher implicitly changes the request into a lock, if the colliding lock is released. The dispatcher uses a priority list to find the optimum user process.

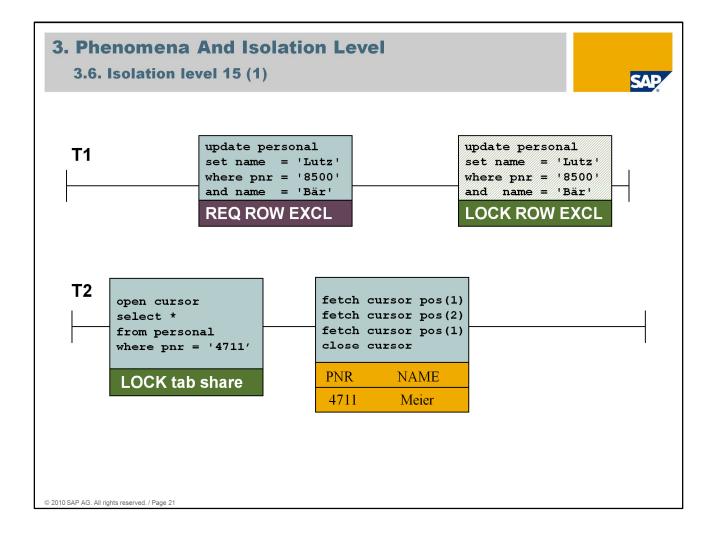

If you specify the isolation level 1, then a shared lock is assigned to the transaction for a read row R1 of a table.

Transaction T2 cannot get the exclusive lock because the Share lock on row R1 (4711/Meier) has not been released.

Transaction T2 requests a LOCK ROW EXCL

In NetWeaver (Java stack), data sources are used for the application logon. These data sources can be configured. You can freely choose the isolation level. If the data source does not specify an explicit isolation level, default isolation level 1 (read committed) is used.

There exists more isolation level which will be explained in the slides. In this session we won't explain those isolation level because they are not used in SAP Application environments by default.

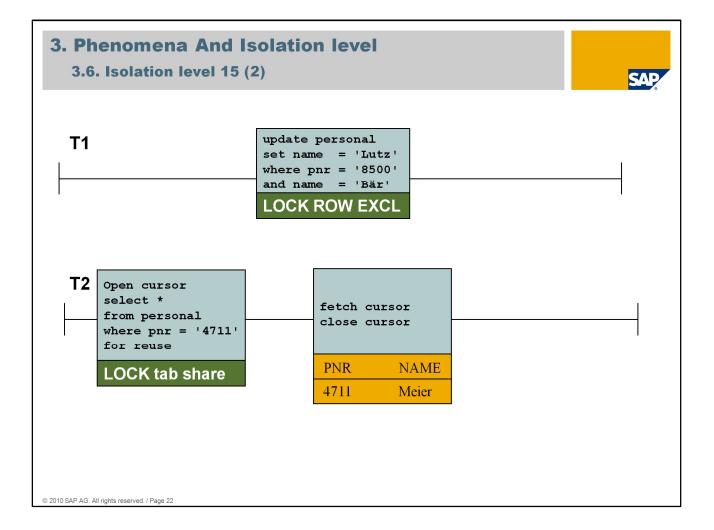

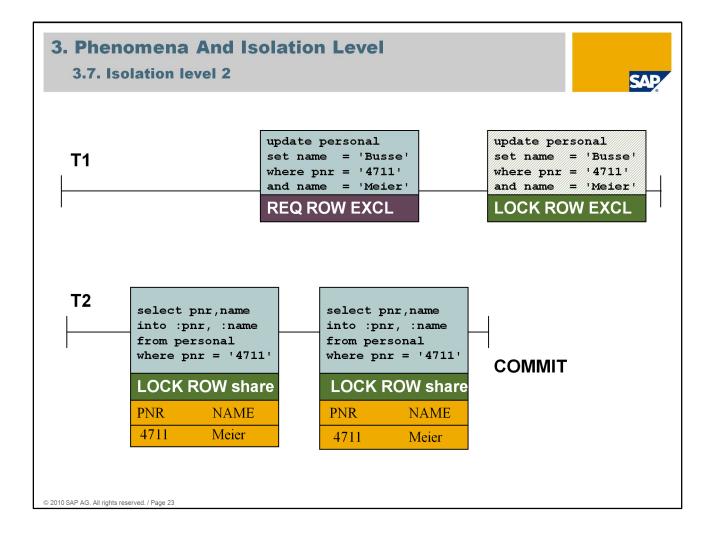

Isolation level 15 ensures that the result set does not change as long as it is being processed.

Reading backwards and positioning the pointer in the result set generates unique results.

For all SQL statements, the behavior described for isolation level 1 or 10 also applies for isolation level 15: The only difference is that with isolation level 15, shared locks are requested for all the tables addressed by the SQL statement before processing starts. If the SQL statement generates a result table, which is not physically stored, then these locks are not released until the end of the transaction or when the result table is closed. Otherwise, the locks are released immediately after the SQL statement is processed.

When inserting, changing or deleting rows, the exclusive locks are assigned implicitly to the transaction for the relevant rows that are not released until the end of the transaction.

Isolation Level 2 safeguards against the "Non Repeatable Read" phenomenon. A record that is read multiple times within a transaction always contains the same values.

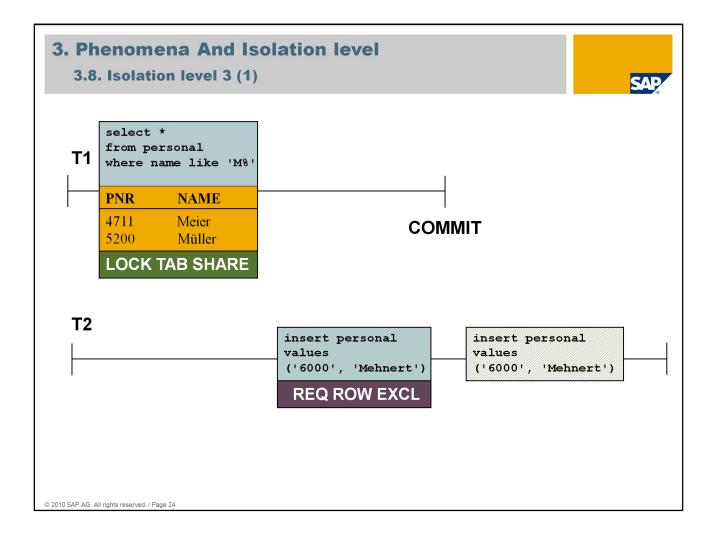

If you specify the isolation level 2 or 20 (repeatable), then shared locks are requested implicitly for all the tables addressed by an SQL statement data query before processing starts.

If an SQL statement generates a result table, which is not physically saved, then these locks are not released until the end of the transaction or when the result table is closed. Otherwise, the locks are released immediately after the SQL statement is processed.

The table shared lock is not assigned to the transaction with SQL statements, where exactly one row in a table is processed that is determined by key specifications or using CURRENT OF <result_table_name>.

In addition, an implicit shared lock is assigned to the transaction for each row read while an SQL statement is being processed. These locks can only be released using an UNLOCK statement or by ending the transaction.

When inserting, changing or deleting rows, the exclusive locks are assigned implicitly to the transaction for the relevant rows that are not released until the end of the transaction. No locks are set for the whole table, however.

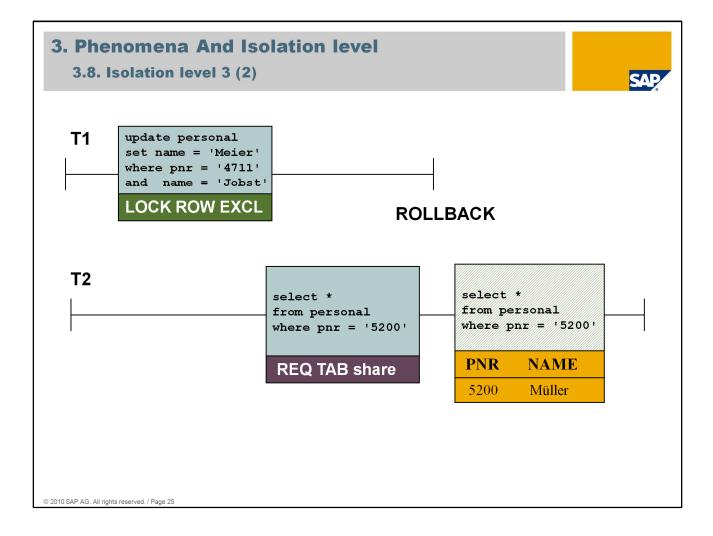

If you specify the isolation level 3 or 30 (serializable), then a table shared lock is implicitly assigned to the transaction for every table addressed by an SQL statement.

These shared locks can only be released by ending the transaction. This table shared lock is not assigned to the transaction with SQL statements, where exactly one row in a table is processed that is determined by key specifications or using CURRENT OF <result_table_name>.

Isolation level 3 safeguards against three types of access anomalies:

- Dirty Read
- Non Repeatable Read
- Phantom

When inserting, changing or deleting rows, the exclusive locks are assigned implicitly to the transaction for the relevant rows that are not released until the end of the transaction.

For system monitoring transaction *DBACockpit* (or *DB50* in older SAP releases) can be used if an ABAP Stack or a Solution Manager is available.

MaxDB system tables can also be used for analysing lock situations but is less comfortable than using the transaction described above.

The database console program x_cons can be directly used on OS level or in transaction *DBACockpit*. This tool is used for more detailed analysis directly on the database. Tasks which are holding or requesting locks are shown in status *Vwait*.

Two of three examples in this demo session can be reproduced using the SAP MaxDB tutorial, which is available with each SAP MaxDB Software version. The toutorial can be loaded with *Database Studio -> Administration Tasks -> Load Tutorial*.

To reproduce the demo examples you have to change the Database Studio preferences as follows:

Start Database Studio and choose:

Window -> Preferences -> Database Studio -> Editors -> SQL

Automcommit has to be switched off.

Isolation level must be set to *Read Uncommitted* (Dirty Read).

After these changes were applied each new SQL Editor inherits this environment.

To create a lock situation a minimum of 2 transactions are necessary. For the first example in this expert session we are using table *hotel.customer:*

select * from hotel.customer

With the following update command the first name of customer with cno= 3000 will be changed from Jenny to Jennie.

update hotel.customer set firstname = 'Jennie' where cno = 3000

This SQL statement is not committed. The system is running in isolation level 0.

In the next slide we check which value for firstname is displayed by the second transaction.

We open a second transaction (Editor 2) and check the content of table *hotel.customer*.

Remember that Transaction 1 is still not committed or rolled back.

select * from hotel.customer

The select is working no share lock has to be set in isolation level 0.

The system is reading uncommitted therefore we already see the changed value of firstname = ,Jennie'

Next step is to check the lock overview in transaction *DBACOCKPIT* (see next slide)

4.1. Monitoring lock	situations: DBACOCKPIT Lock Overview

Each transaction which wants to change records has to set locks on the records. In this example we have 2 transactions which want to change records. We have 2 entries in the lock overview.

Task ID 68 (which is the second SQL session which wants to change the address) wants to have an exclusive lock (*Lock request*). Task ID 65 (which is the first transaction which changes the first name) has the exclusive lock on the record with cno=3000.

To find out if those transactions are both trying to change the same records the *DBACOCKPIT* -> *Performance* -> *SQL Locks* -> *Waits* has to be used.

4. System Monitor 4.1. Monitoring lock	ing situations: DBACOCKPIT Lock Waits
Exclusive SQL Wait Situations

<u> </u>	
	▷ S70 (1) (000) 🖻 pwdf2763 INS

In transaction *DBACOCKPIT* -> *Performance* -> *SQL Locks* -> *Waits* the system shows which transactions are holding locks and which transactions are requesting those locks.

In the example of this session:

- Task ID 65 has a row_exclusive lock (Lock Type) on table customer
- Task ID 68 is requesting a row_exclusive lock (Lock request) on the same record

Task ID 68 is in status waiting (*Waiting*). The *Lock Wait Time* displays the remaining wait time for this lock (in seconds). Initial lock wait time is the value of parameter **RequestTimeout**. The database parameter RequestTimeout defines how long a transaction is waiting at a max for the assignment of a lock. If this wait time has expired before the lock is assigned, the transaction terminates with an error *,-51 Lock request timeout*'.

TaskID 68 will get the lock as soon as Task ID 65 gave the lock free again (after COMMIT or ROLLBACK). If Task ID 65 does not give the lock free again in the remaining lock request wait time, Task ID 68 will get an error message ,-51 Lock request timeout'.

No locks exists anymore when both transactions in the database EXPERTDB have been closed with COMMIT or ROLLBACK.

To monitor lock situations you can use transaction *DB50* or *DBACOCKPIT*.

When you are working in an NON-SAP-Environment you can use the SAP MaxDB system tables to monitor lock situations.

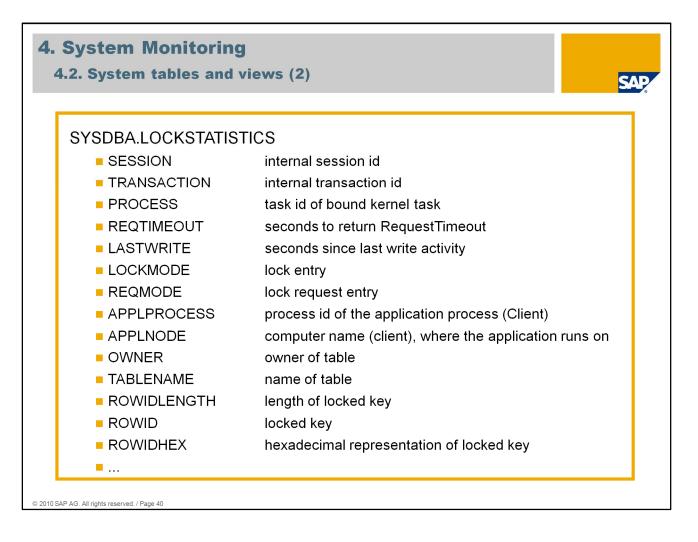

DOMAIN.LOCKS or DOMAIN.LOCK_HOLDER are showing all locks which currently exist in the system.

The output of these system tables is shown in the transaction *DBACOCKPIT* -> *Performance* -> *SQL Locks* -> *Overview*.

System table DOMAIN.LOCK_REQUESTOR lists all locks which are currently requested.

System table DOMAIN.LOCK_WAITS lists all owners of current locks related to current lock requests.

The output of this system table is shown in the transaction DBACOCKPIT -> Performance -> SQL Locks -> Overview.

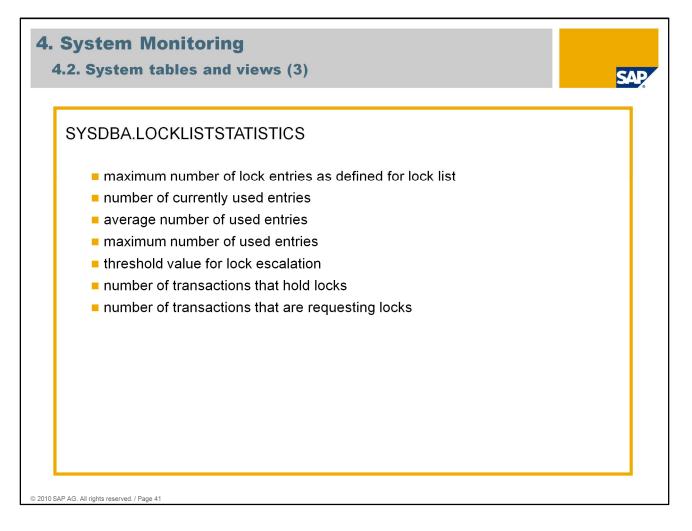

The system table LOCKSTATISTICS describes the current lock entries and entries for lock requests.

Using the system table LOCKSTATISTICS you can determine the following database information, among other things:

- All locks that are held on a table
- All locks that the current user is holding during his database session (if this is the current user (DBA user) or database system administrator (SYSDBA user), then all locks are displayed).

Users that belong to other user classes only see the locks held by that one user.

You will find a table description of all columns in the system table manual.

The following only lists particular columns:

- MAXLOCKS contains the number of available locks in the lock list
- USED ENTRIES contains the number of entries for locks and lock requests
- AVG USED ENTRIES contains the average number of entries used for locks and lock requests
- MAX USED ENTRIES contains the maximum number of entries used for locks and lock requests
- LOCK ESCALATION VALUE contains the number of table rows from which the lock rows are converted into table locks (lock escalation)
- LOCK ESCALATIONS shows the number of escalations occurring so far.
- LOCK COLLISIONS shows the number of collisions occurring so far for lock requests.
- DEADLOCKS shows the number of deadlocks that have been recognized and resolved by the database system so far.
- TRANSACTIONS HOLDING LOCKS contains the number of transactions with assigned locks
- TRANSACTIONS REQUESTING LOCKS contains the number of transactions requesting locks

What is a lock escalation?

A lock escalation is the conversion of line locks into a table lock.

The MaxDB parameter **MaxSQLLocks** specifies the maximum size of the lock entry list. In this list, record locks and table locks of all users as well as their lock requests are managed. **If the record locks of one transaction take up more than 20% of the lock list for a table, the system carries out a lock escalation**. In this process, the record locks are converted to a table lock.

As of Version 7.6.03, an additional threshold (parameter **RowLocksPerTransaction**) was introduced for lock escalations. If a transaction fills more than 50% of the lock list with line locks, the lock escalation is carried out for the table whose record is to be locked when this threshold value is exceeded. The default value of parameter RowLocksPerTransaction is 50 %.

The system carries out lock escalations to prevent an overflow in the lock entry list. Table locks may affect concurrent users who have lock requests.

You can increase the number of possible record locks for each user and table by increasing the value of the parameter **MaxSQLLocks**.

You should increase the value of MaxSQLLocks if in transaction DBACockpit -> Performance -> Activities Overview

Lock Activity shows:

- Available Entries -> Average set is similar to the value for MaxSQLLocks
- Available Entries -> Maximum set is identical with the value for MaxSQLLocks
- Escalations is higher than zero

Notice: The values are initialized with each shutdown of the database.

For each lock that has been defined using **MaxSQLLocks** the database takes up 200 to 300 bytes of main memory during the restart. The size of the entries depends on the database versions and the operating system. If you want to determine the exact memory consumption use the original value for MaxSQLLocks to start the database. Use the operating system to determine the memory consumption of the database process. Set MaxSQLLocks to the planned new value and set the database to offline status and then to online status. Use the operating system again to determine the memory consumption and calculate the difference between the key figures determined.

In SAP environment the values of MaxSQLLocks are between 500.000 and 1.500.000.

In Business Warehouse systems values of 2.500.000 are not seldom.

A deadlock occurs if two or more users impede each other due to set locks and can no longer work as a result.

Two or more transactions hold locks and request further locks that are already held by the other transaction.

Deadlocks are detected by the database up to a certain depth. The system issues an error message for the user who triggers the deadlock. The deadlock is removed.

The database cannot recognize all deadlocks, for example, if shared locks are involved. A deadlock that is not detected by the system is removed by timeouts.

The database parameter **DeadlockDetectionLevel** defines the maximum depth of search for the deadlock detection with SQL locks.

If this database parameter is set to value 0, the deadlock detection is deactivated (in other words, deadlocks are removed only by **RequestTimeout**). A value that is higher than 0 defines the depth of search. Up to the specified depth of search, deadlocks are detected and immediately removed. The initial value for the deadlock detection is 4. A higher value results in considerable costs. Consider using a higher value only if an application triggers serious deadlock problems that cannot be solved in the application.

The default value of parameter **DeadlockDetectionLevel** is 4.

In the following example we have 2 transactions. Each transaction is holding a row exclusive lock on a table and is requesting an exclusive lock which is held by the other transaction.

First transaction is changing the price of single rooms for hotel 1413 in table *room*. This change is not committed yet.

Transaction 1 is holding a row exclusive lock.

While transaction 1 is waiting for the row lock exclusive on table *reservation* which is hold by transaction 2, transaction 2 wants to do an update on table *room*. The number of free rooms has to be reduced.

Because transaction 1 is holding a row exclusive on the same record of table *room* transaction 2 cannot get the row exclusive.

The deadlock detection mechanism will avoid this deadlock situation

- transaction 1 is holding the lock transaction 2 is waiting for
- transaction 2 is holding a lock transaction 1 is waiting for

with an implicit rollback of the second SQL command of transaction 2 (error message '-60 work rolled back, DEADLOCK DETECTED').

The database parameter *DeadlockDetectionLevel* defines the maximum depth (here: level 4) of search for the deadlock detection with SQL locks.

To check what happens during a deadlock the DeadlockDetectionLevel is switched off by setting the parameter to the value 0.

If the deadlock detection is switched off deadlocks will only implicitly be solved with request timeout mechanism.

Transaction 2 is changing the arrival date for the room no 15 of hotel 1413 in table *reservation*.

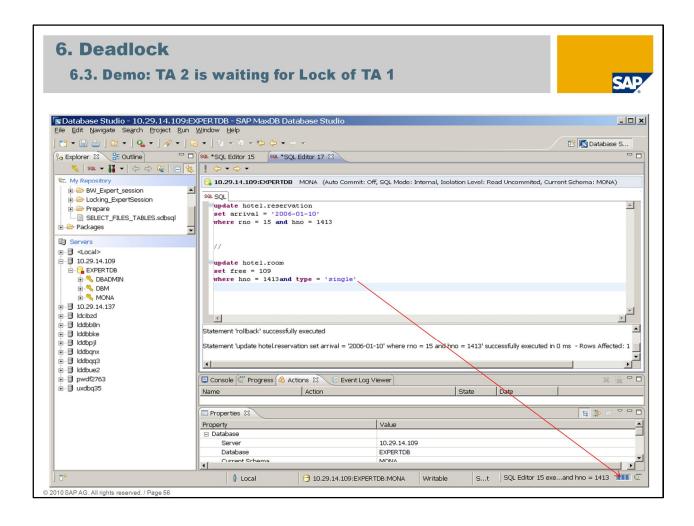

Transaction 2 is holding a row lock exclusive on table *reservation*. This change is not committed yet.

There is no wait or deadlock situation yet. We have 2 row exclusive on two different tables.

Transaction 1 is starting the second SQL command. Table *reservation* should be updated. The departure date of room no. 15 of hotel 1413 will be changed.

Because of transaction 2 is already holding the row lock exclusive on this row, transaction 1 has to wait. A request row lock is set.

While transaction 1 is waiting for the row lock exclusive on table *reservation* which is hold by transaction 2, transaction 2 wants to do an update on table *room*. The number of free rooms has to be reduced.

Transaction 1 is holding a row exclusive on the same record of table *room* therefore transaction 2 cannot get the row exclusive.

Deadlock detection is switched off therefore both transactions are waiting for each other.

When the deadlock detection is switched off this deadlock situation will be solved when the request timeout is reached. One of those transactions is rolled back.

The deadlock situation can be solved implicitly by the request timeout, which is configured with parameter **RequestTimeout**. In SAP environment the parameter RequestTimeout is set to 3600 seconds.

When the wait time of request timeout is reached the transaction which is requesting the lock will be rolled back with error message '-51 Lock request timeout'.

For this session we don't want to wait 1 hour until the deadlock will be solved implicitly. The *Task Manager* can be used to kill one of the in the deadlock involved tasks (=transactions).

Another important issue to know is how to analyze system blocking situations. To solve a blocking situation you need to know which application is responsible for the lock which blocks the system.

In transaction *DBACockpit -> Performance -> SQL Locks -> Overview* we have 3 transactions (Task ID: 63, 65, and 62).

All 3 transactions are started on the same application server. The application ID (*Appl. ID*) is important to know for further analysis.

The application ID is the application process ID (application PID) of the work process which is connected to the database task.

Workprocess:	Database Task:
5424	63
5400	65
3076	62

Application 3076 has an exclusive lock on table room.

Application 5400 and 5424 are requesting an exclusive lock on table room.

All applications which are involved in this hanging situation are running on the same application server. To get an overview transaction SM50 (Process Overview) on the application server pwdf2763 is used to get more detailed information.

If applications on several servers are involved into a hanging situation transaction SM66 (Global Work Process Overview) is used for detailed analysis.

Work process 0 has application PID 5400, which is in status *Running*. Currently in action Update on table *room*.

Work process 1 has application PID 3076, which is in status *Running* as well. Currently doing a sequential read on table *city*.

Work process 2 is not relevant for the blocking situation.

Work process 3 has application PID 5424, which is in status *Running* as well. Currently doing an Update on table *room*.

E ^r <u>Waits Edit Goto System Help</u> ♥ I IIIIIIIIIIIIIIIIIIIIIIIIIIIIIIIIII	
Bystem Configuration OB Connection System EXPERTOB	Image: Contract of the contract

To get the information which transaction is waiting for which lock transaction *DBACockpit -> Performance -> SQL Locks -> Waits* is used.

Application PID 3067 (Work process 1) is holding the exclusive lock and both Task ID 63 (WP 3) and Task ID 65 (WP 0) are waiting for this lock.

From the output of transaction SM50 task ID 62 (WP 1) is doing a sequential read on table *city* and from database point of view even has a lock on table *room*.

This looks like in the ABAP program after an update, insert or delete there is no commit work.

This may not happen in a regular SAP environment where the application programmers are using the SAP Enqueue mechanism to lock and unlock table accesses.

This can only happen when you are using native SQL in your ABAP coding, which is not recommended.

Additionally transaction *DBACockpit -> Performance -> Kernel Threads -> Task Manager -> Active Tasks* is used to check the status of each involved tasks from database side of view.

Only those tasks are listed in Active Tasks which are active on the database level.

On database level Task ID 63 and 65 are in status *Vwait*, which means they are waiting for SQL locks.

Task ID 61 is the Task Manager itself, so this is not relevant for the analysis of the blocking situation.

The third task ID 62, which is involved into the blocking situation is missing in the *Active Tasks.* Why?

It looks like this task is doing nothing in the database kernel.

An overview about the status of all user tasks can be seen with *User Tasks*. Task ID 62 is in status *Command wait*. Therefore there is no entry in *Active Tasks*.

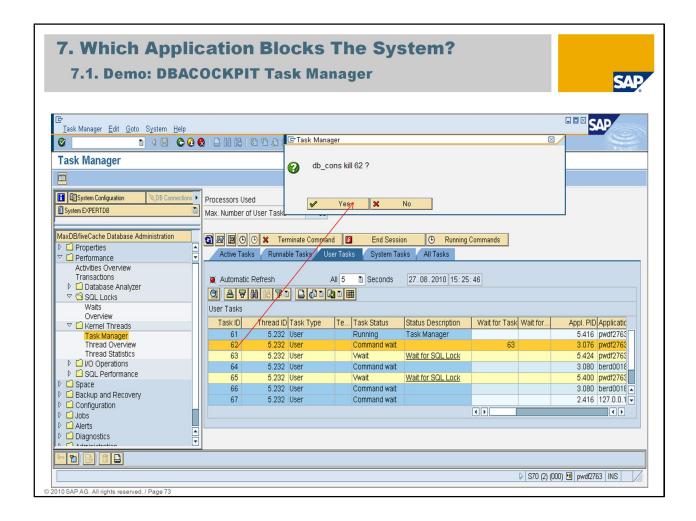

A Task which is in status *Command wait* is doing nothing on the database. The task is waiting for the next application command which is sent to the database.

Conclusion this task must be terminated to get the blocking situation solved.

0	_	5 T To 3	am/Session						81 🗮	2 0	}			S.
Pro	oce	ss O	/erview											
5	•	3 🥋	37 4				17 🞝 (2

Notice: Even when you see in transaction SM50 that application 3076 (Task ID 62) is busy with sequential read on a table, this does not mean that the application is busy on the database.

Therefore always use the MaxDB *DBACockpit (or DB50) -> Task Manager* to analyze and solve blocking situations.

With transaction *DBACockpit -> Performance -> Kernel Threads -> Task Manager* Task ID 62 will be killed by using *End Session*.
